SUMMARY
This article aims to make reference to some recent mourning aspects considered risk factors for cardiovascular disease, specifically the Takotsubo cardiomyopathy. The objective was to describe the stress from the death of a loved one combining it to the possibility of occurrence of Takotsubo cardiomyopathy through the perception of a traumatic event by the cortex, which triggers the subcortical brain circuit affecting the endocrine response. Given the growing acknowledgement of this cardiomyopathy, it is possible to contextualize the nutritional behaviours and decisions surrounding it, whose benefits must exceed the condition of temporary cardiac dysfunction and extend to food choices that have some influence in the limbic system. It is a descriptive analysis that aims to problematize the theme into reflections based on this experience, considering the foundation with the science of nutrition.

INTRODUCTION

Faced with death, the constancy of intense affective-emotional reactions is what classifies the event as a traumatic stressor. The difficulty in coping with the death of a loved one favours the intensity and duration of reactions mediated by biophysiological and psychological mechanisms that may be more devastating to the organism, allowing the manifestation of Takotsubo cardiomyopathy (TC).

Although the pathophysiological mechanisms of TC are not fully understood, its association with high stress has focused attention on the autonomic nervous system, whose evidence suggests that it is a reflex response controlled by this system - since patients with Takotsubo have higher levels of catecholamine than those with acute myocardial infarction; endomyocardial biopsy is typical of this elevation; and myocardial dysfunction induced by increased catecholamine is the most likely mechanism for TC. Because of this, the exacerbated response of catecholamine is pointed out as a central factor for the occurrence of this cardiomyopathy. In this follow-up, consideration is given to the organic effects to the myocardium in line with the impact of death of a loved one, which has implications on hormonal mediators. Based on this premise, it was important to discuss the effects of recent mourning on the cardiovascular system from the perspective of Takotsubo cardiomyopathy and its repercussion on nutri-
tional management, based on the neuroendocrine implications associated with the trauma of losing a loved one. It should be noted that TC is referenced by other names, among which the expression Broken Heart Syndrome is included in the scope of this article.

METHODS

A search for scientific articles with the topics of Takotsubo Cardiomyopathy and Mourning was carried out. The following descriptors were searched in the Capes journal portal and the Science Direct and SciELO databases: “Takotsubo syndrome”; “Takotsubo cardiomyopathy”; “broken-heart syndrome”. Other sources of research were: “death” and “stress”; “mourning” and “neuroendocrine responses”; “effects of bereavement”; “bereaved parents”; “grieving process”. Publications that did not meet the criteria of interest were excluded from the theoretical reference. The bibliographic research was conducted from May to August 2017, without period restriction, given the need for unified information to support this review. It is a descriptive analysis, based on the main heart alterations of the TC, contextualizing the broken heart syndrome in the face of mourning and nutritional management. To further substantiate this descriptive analysis, the content was organized into three sections: Takotsubo cardiomyopathy in mourning; Takotsubo cardiomyopathy from the perspective of the loss of a loved one; and nutritional management in Takotsubo cardiomyopathy.

TAKOTSUBO CARDIOMYOPATHY IN MOURNING

Depending on the particularities of each person, the emotional regulation profile and the affective bonds established between people, the death of a loved one can trigger a strong psychological emotion that can result in cardiac changes. Mourners look for emergency care especially for the fear of having a heart attack. Mourning can increase the risk of acute myocardial infarction (AMI) by up to 21 times, an assertion based on a sample of 1,985 patients, where the increased risk is noted within the first 24 hours after the death of the loved one. As angiographic data were not available, the investigators claim that it cannot be ruled out the possibility that some cases refer to TC. Despite its rarity, an AMI may not exclude a cardiomyopathy of stress, and it could even be its trigger. The TC precipitant commonly falls into the stressful physical or emotional condition, however, the lack of a precedent does not exclude the diagnosis.

Given that there is an association between mourning and loss experience with heart disease, and that in the first few days, weeks and months after the death of a loved one, cardiovascular disease represents an increase in the risk of death during mourning, subtle differences between heart attack and TC deserve appreciation, as the symptoms are similar. In TC, coronary cineangioigraphy does not show significant obstructions indicating that the primary cause is not related to obstructive coronary disease and ventriculography reveals apical ballooning of the left ventricle due to akinesia, with basal hyperkinesia similar to dumbbells or Takotsubo - characteristic image of the syndrome (Figure 1).

In the TC electrocardiogram (ECG) pattern, a greater number of derivations with ST segment horizontal depression in the inferior wall and/or T wave inversion are identified, with a prolonged QT interval, although there are differences in this pattern and the ECG may not be specific. Laboratory tests reveal a slight elevation in the serum concentration of markers of myocardial injury disproportionate to the area affected by the ECG. Levels of B-type natriuretic peptides, which reflect left ventricular systolic dysfunction, are elevated, with values higher than those found in AMI. Although the term stunned cardiac muscle is used to indicate cardiac injury in Takotsubo, the lack of elevation of the enzymes does not exclude the diagnosis.

Other biomarkers have been reported. The
alpha tumour necrosis factor (TNF-α) and the soluble form of its receptors (sTNFR-1 and sTNFR-2) are involved in myocardial dysfunction\textsuperscript{27-29}, although its effects may include adaptive responses to cardiac protection\textsuperscript{29}. The increase of TNF-α is influenced by the plasma concentrations of catecholamines\textsuperscript{30}, in response to its stimulus, other proinflammatory cytokines are released, whose activation occurs early to cardiac alterations\textsuperscript{32}. Despite the clinical importance of cardiac biomarkers, in post-traumatic stress conditions, their dosages should compose routine exams.

Among the care given to the mourners, which need to start early on, attention must be given to the cardiac conditions of these individuals. Greater attention to the established diagnostic criteria\textsuperscript{23,31} in guidelines\textsuperscript{23,31} for TC, aligned with the mourning, can provide the actual dimension of this association.

The literature has presented clinical cases that associate TC with mourning\textsuperscript{32}. A possible link between cognitive emotional processing and vulnerability to Takotsubo syndrome was evidenced in a clinical case, after a domestic discussion, with a history of death of a loved one, six months before the symptoms\textsuperscript{32}. For Redfors et al.\textsuperscript{32}, psychiatric conditions may predispose an individual to develop stress-induced cardiomyopathy in response to a strong stressor. Due to other evidences\textsuperscript{34,35}, a deeper understanding of this phenomenon imposes investigations on the interface: post-traumatic stress due to death of a loved one and biological predisposition to TC.

**TAKOTSUBO CARDIOMYOPATHY FROM THE PERSPECTIVE OF THE LOSS OF A LOVED ONE**

According to Crawford and Schaffer\textsuperscript{36}, the healthy heart has signalling mechanisms through which it responds to metabolic stress with a remarkable degree of efficiency to meet the high demand and plasticity in response to changes, varying in the supply of the energy substrate to provide for homeostatic, mechanical and electrical activities. Dysfunction in contraction and damage appear when this capacity is exceeded\textsuperscript{36}.

In an attempt to explain the pathogenesis of TC, several theories have been proposed. Although the pathophysiology is not fully elucidated, there is consensus about the action of catecholamines\textsuperscript{5,26,37}. For Coupez et al.\textsuperscript{37}, the common denominator in TC is catecholaminergic stress. High concentrations of catecholamine may cause damage to the myocardium\textsuperscript{4} through the supraphysiological activation of β1 and β2 beta-adrenergic receptors, by activating adenylyl cyclase by interacting with stimulatory G protein, elevating the formation of intracellular cyclic adenosine monophosphate that activates protein kinase A – this phosphorylates membrane proteins, increasing the influx of calcium into cells and oxidative stress\textsuperscript{7}. This would lead to disturbance of ventricular contraction and function, which may decrease the viability of cardiac myocytes\textsuperscript{26}. The interaction of this mechanism with other individual predisposing factors may favour TC.

Among the factors that can trigger an overload of catecholamine in the body is the death of the loved one and the *trauma* that occurred during this event. The perception of a traumatic event by the cortex triggers the subcortical cerebral circuit, through the structures that control the emotions and the functions of the visceral systems, whose activation triggers the release of norepinephrine in the hypothalamus\textsuperscript{5}. Therefore, the release of epinephrine from the marrow of the adrenal gland is induced\textsuperscript{26}. Dealing with the news of death and the loss of a loved one is an *aggression of a psychogenic nature*. In this circumstance, the fundamental hormonal element of organic reactive response is the corticotrophin releasing hormone\textsuperscript{38}, in response, the pituitary gland releases the adrenocorticotropic hormone (ACTH), which stimulates the secretion of corticosteroid hormones and catecholamine by the adrenal glands\textsuperscript{2}. Catecholamine induce myocardial adrenergic stimulation; the excess release induces toxicity in cardiac myocytes because it causes a calcium overload in myocytes\textsuperscript{7}, leading to alterations in cardiac contractility - a more accepted proposition for TC\textsuperscript{26} (Figure 2).

Hypercortisolism is associated with AMI\textsuperscript{19} and other heart diseases\textsuperscript{40}; it induces proteolysis and lipolysis\textsuperscript{2}; and may involve the increase of visceral fat that is associated with metabolic disorders\textsuperscript{41}. The organic imbalance appears when the changes are repetitive, coming from an excessive activation, plausible condition of occurrence in the bereavement of children and partners of a lifetime, because, in the psychic complexity of these mourning, the expected hormonal compensatory response will not always occur\textsuperscript{2}. Not living with a child anymore (due to death) emotionally destabilizes parents - reactions and orders arise as a direct consequence of stress or continuous trauma\textsuperscript{42}, altering the endocrine response,
which in turn has reflexes in other metabolic pathways, deserving more investigations since it portrays a differentiated issue of mourning in confrontations and adaptations. On the other hand, the loss of a daily present partner, depending on affective attachment, emotional shock and cardiac conditions, may favour the occurrence of TC, especially at more advanced ages.

Effects of mourning state and grief time on cortisol response revealed a significant interaction, indicating differences in cortisol response pathways in mourners and non-mourners. The increase of cortisol by psychological disorders in non-mourners is less expressive than in mourners. The interaction of the significant loss of the loved one with the grief time evidenced the persistence in the increase of this hormone, having differences in values, as a result of the death. It may be hypothesized that, in the case of recent mourning, the vulnerability to TC lies in the abnormal activation of the hypothalamus-pituitary-adrenal axis with the constancy of intense affective-emotional reactions; and the cause of the death of the loved one is an aggravating factor, because it intensifies the psychic trauma - “feeding” the psychological distress, since it recalls strong and painful memories that constitute constant stressful stimuli. Under conditions of excessive sympathetic stimulation, one must also consider the possibility of reduced parasympathetic modulation, whose impaired control may play a relevant role in TC.

NUTRITIONAL MANAGEMENT IN TAKOTSUBO CARDIOMYOPATHY

Initially, the goal is to alleviate cardiac overload by opting for the nutritional management that apply to this condition. Therefore, restriction of salt (sodium chloride) in cooking and of salt-based condiments, non-addition of salt in ready-made foods, restriction of industrialized foods with high sodium content in their composition and the control of water intake are crucial recommendations whose effects on the body must be carefully monitored. To give a pleasant flavour to the meal, preferably combine spices referenced with cardioprotective properties with aromatic herbs.

Due to myocardial injury, include food sources of phenolic compounds, which, depending on their absorption and metabolism, can modulate the expression of various biomarkers, attenuating oxidative stress and reducing proinflammatory cytokines. As for fruits, preference should be given to those with purple and red colors, citrus and oleaginous, because they contain a higher content of phenolic compounds. Calculate daily fructose intake to avoid that its excess can contribute to the increase of uric acid - via degradation of adenosine monophosphate (AMP) from adenosine triphosphate (ATP) generated in the metabolism of fructose, which is converted into uric acid. Although uric acid is considered an important antioxidant in human plasma, supranormal levels in the blood have repercussions on cardiovascular function, hyperuricemia inhibits the release of nitric oxide, which activates the renin-angiotensin system, constituting an important collaborator in determining cardiovascular risk, and it also has an impact on the diagnosis of the metabolic syndrome. Moderate fructose consumption, ≤50 g/day, has no harmful effect on health; excesses can exert harmful effects on metabolic analogies to ethanol, differing only by non-metabolization in the central nervous system.
However, due to TC, it is prudent that the ingested fructose is between 25 and 30 g daily. Consult the fructose content in fruit types to establish the quantities and size of the portions and avoid processed foods containing sucrose or fructose-rich corn syrup. In order to keep the serum concentration of uric acid in the normal range, also designate, in daily portions, foods with a more expressive content of purines - the main precursor of uric acid.

Ensuring homeostasis of the enteric microbiota is another behaviour known for its beneficial effects. The combined use of pre-and probiotic foods has a hypolipidemic effect and is suggested to reduce plasma concentrations of toxins in plasma and, given the ability of bacteria to produce and recognize neurochemicals, it has been indicated as a therapeutic adjuvant for brain chemistry. The replacement of probiotics (through diet) is done with the daily intake of products such as fermented milk and kefir, and of prebiotics as ingredients in the culinary - field with increasing evidences in nutritional benefits. It is recommended to include pre and probiotic products duly regulated by the competent bodies of each country to recommend those with substantiated claims.

Balance amounts and types of fats (monounsaturated, polyunsaturated and saturated) provided by dietary intake, through analysis of tests that results in individual guidelines and restriction of trans fats. Adequate consumption of polyunsaturated fatty acids contributes to a decrease in the hepatic production of VLDL (very low density lipoprotein), improvement in antiarrhythmic effects, among other benefits. Up to 10% of the diet caloric value of polyunsaturated fatty acids diet is recommended in combination with foods that contain antioxidants - excessive intake may lead to increased lipid oxidation, decreasing HDL-c (high density lipoprotein cholesterol). Polyunsaturated fats, when exposed to heat and oxygen, favour processes of oxidation and other chemical changes. Culinary methods that use high temperatures and low humidity (frying, roasting or grilling) potentiate the formation of advanced glycation products (AGEs), which, in excess, favour injuries to the tissues, predisposing the organism to the progression of diseases, including cardiovascular diseases, causing oxidative stress and increasing the expression of inflammatory mediators. Gentle preparation methods with high water activity generate lower levels of these compounds and restrict cooking fats. Although the formation of AGEs is predominantly endogenous in the body, they can be introduced by exogenous sources especially incorporated in foods. The diet to attenuate myocardial injury should add to the dietary recommendations for fats and cardiovascular health the control of dietary AGEs intake, in order not to exceed the body’s capacity to degrade these compounds, benefiting recovery.

If there is heart failure and volume overload, the use of diuretics is administered, in these cases, ensure the presence of food sources of potassium in the composition of the meals, coupled with adequate monitoring in the organic response to avoid other electrolyte disturbances.

In view of the reestablishment of cardiac functions, the conducts inherent to the limbic system must be instituted. The limbic system is a complex combination of various structures of the brain that receives sensory stimulation, which is translated into emotional and psychological expression, regulating various functions in the organism. If the balance in the chemistry of this system interferes with emotional health, the contribution of precursors of neurotransmitters responsible for the feelings of well-being must be restored through diet. When the person suffers a significant loss, such as the death of a child, the sadness can be intense and prolonged, characterizing a condition of mental depression or adjustment disorder. A balanced supply of these chemical transmitters is essential so that the body can respond better to the stressor event. For example, to benefit serotonin production, consider food sources of tryptophan in balance with carbohydrates (aiming to increase the uptake of tryptophan in the cerebrospinal fluid in competition for the transporter that crosses the blood-brain barrier) and other nutrients (folic acid, pyridoxine and magnesium) for conversion of tryptophan into serotonin. In mourners, the replacement of nutrients and food components that have a beneficial influence on mental health needs to be implemented and with the combination of foods that provides the best response.

However, the treatment of patients with TC should be individualized according to their clinical, psychic and nutritional conditions. This requires the application of a more specific clinical-nutritional protocol, paying attention to diet and food components referenced as protectors of heart injury, as well as traumatic situations triggering this syndrome, seeking to identify the basis of each person’s disturbances. If TC resulted from the loss of a loved one, cover the emotional stressors associated with this pecu-
liarty, know the cause of death, the particularities of mourning, behavioural changes instituted after the death of the loved one, being aware of the changes that may have come up in sleep, diet, body weight and perimeter. Among the multiplicity of factors involved (psychic and physiological) in the genesis of the psychosomatic phenomenon, the situations of losses preceding the illness are more emphasized, which redirects attention to the mourners because of their vulnerability to becoming ill. Considering the connection of emotional stress with the heart, depending on the psychic conditions of the bereaved, in addition to grief therapy and cardiac evaluation, it is reasonable to evaluate the need for pre-treatment with medication indication and referral to nutritional care, mainly in clinical cases of inability or refusal to eat. The way we deal with death and mourning has implications in eating behaviors, with serious consequences to health, and restoring, through food, benefits to the mind and heart, is realizing that, in the face of individuals destroyed by loss and with symptoms of anhedonia, nutritional management require gradual adaptation. Cases of stress-induced cardiomyopathy have been described in individuals with eating disorders, who reach higher severity because they are associated with prolongation of the QT interval due to electrolyte imbalances and hypoglycemia. It is conceived that cardiovascular research in mourners needs to be carried out, especially in the presence of well-defined behavioural and mood changes, and when severe diet restriction is noted.

FINAL CONSIDERATIONS

Deepening the psychic issues of mourning requires a careful look at individual differences in reaction to death. Mourning is not a process that progresses in a linear way, therefore, it deserves the deepening in studies that ally its effects to cardiac alterations.

In mourners, due attention to the cardiac symptoms of Takotsubo cardiomyopathy should also be part of the clinical care protocols, in order to guarantee more specific investigations directed to this syndrome. Because this cardiomyopathy has a strong association with emotional stress, greater attention in this recognition could contribute to the notification of clinical cases in Brazil.

The science of nutrition is inserted in this context because it favours, together with hemodynamic therapy and coping with mourning, not only benefits for the reestablishment of cardiac function, but also extends to diet planning applied to mental health and nutritional health.
